SUMMARY

Introduction: Protein-energy malnutrition in Crohn’s disease (CD) has been reported in 20 to 92% of patients, and is associated with increased morbidity and mortality and higher costs for the health system. Anti-TNF drugs are a landmark in the clinical management, promoting prolonged remission in patients with CD. It is believed that the remission of this disease leads to nutritional recovery. The effect of biological therapy on body composition and nutritional status is unclear.

Method: Prospective study of body assessment by bioelectrical impedance method in patients with moderate to severe CD undergoing treatment with infliximab. The main outcome was the body composition before and after 6 months of anti-TNF therapy.

Results: There was a predominance of females (52%) with a mean age of 42±12 years. Most patients were eutrophic at baseline and remained so. There was an increase in all parameters of body composition after anti-TNF treatment: BMI (22.9±3.2 versus 25±3.8; p=0.005), waist circumference (88.1±6.7 versus 93.9±7.7; p=0.002), lean mass index (17.5±2.2 versus 18.2±2.3; p=0.000) and fat mass index (5.5±2.3 versus 6.8±2.3; p=0.000). Phase angle remained unchanged (6.2 versus 6.8; p=0.94).

Conclusion: After therapy with IFX, all components of body composition increased, except for phase angle. The substantial increase in fat mass index and waist circumference led to concern regarding cardiovascular risk and, thus, to the need for further studies.

Keywords: Crohn’s disease, body composition, biologics.

INTRODUCTION

Crohn’s disease (CD) is a chronic, transmural, immunemediated condition that affects the gastrointestinal tract with a potential for involvement of various organs with extra-intestinal manifestations. The etiology of CD remains unclear, but it is believed to be multifactorial with associated environmental, genetic and immunological factors. The overall prevalence is 5 to 50 cases per 1,000 inhabitants, with a predominance of Caucasians.1 An estimate of the prevalence in the city of São Paulo, Brazil, reported the occurrence of 14.8 cases per 100,000 inhabitants.2

Protein-calorie malnutrition (PCM) has been reported in about 20 to 92% of patients with CD.3-7 Many factors contribute to PCM and deficiency of macro-nutrients, vitamins and minerals in this group of patients. Changes directly related to disease activity, such as inflammatory changes in the intestinal epithelium, as well as previous intestinal resections, may be responsible for malabsorption of nutrients and vitamins (such as vitamins A, D, E, K and B12). Pain, present at times of disease exacerbation, and increased inflammatory mediators, such as tumor necrosis factor, are associated with anorexia and cachexia.8 In addition to these factors, the therapy used in the
treatment of CD can be associated with certain side effects that negatively affect the nutritional profile of these patients.\textsuperscript{9} Also, increased nutritional requirements as a consequence of inflammatory activity and complications of the disease may corroborate for weight loss.\textsuperscript{10}

It is well-known that weight loss, low body mass index (BMI) and PCM predominate in patients with moderate to severe CD, especially those admitted to hospital, being associated with higher mortality, longer hospitalization and increased health costs.\textsuperscript{11} Zhang et al. showed that the BMI is inversely related to intra-abdominal infectious complications in patients with CD undergoing an elective surgical procedure.\textsuperscript{12}

Location, phenotype, severity and disease activity appear to be directly related to impairment of nutritional status. Disease activity is related to increased basal energy expenditure, weight loss and anemia.\textsuperscript{13,14} In addition to malnutrition, changes in body composition such as the occurrence of sarcopenia have been described in patients with CD.\textsuperscript{15-18} Schneider et al. describe the occurrence of sarcopenia in 60\% of patients with CD even during clinical remission.\textsuperscript{18} Loss of lean mass (LM) has been associated with worsening of bone mineral density, increased morbidity, loss of muscle strength, and increased risk of infectious complications.

Traditionally, nutritional status has been evaluated based on objective parameters (anthropometric measures, skinfolds, clinical questionnaires, laboratory tests) and complementary methods already well-established for the evaluation not only of nutritional status, but also of body composition (dilution methods, dual-energy absorptiometry and electrical bioimpedance). Bioelectrical impedance analysis (BIA) is a method widely used to estimate body composition and nutritional status in several clinical populations because it is a simple, fast, noninvasive method with reproducible results.\textsuperscript{19} Not only does it determine the fat mass (FM) and the fat-free mass (LM), the four-part model also allows the evaluation of the degree of cellular damage by determining a phase angle (PA), which has been considered a promising tool to assess the nutritional status and indicate prognosis.\textsuperscript{19-21}

Biological therapy has dramatically changed the treatment of inflammatory bowel diseases (IBDs). This therapy is based on a monoclonal antibody that acts directly by blocking tumor necrosis factor alpha (TNF-\(\alpha\)) and is effective in reducing inflammation, improving symptoms and inducing intestinal mucosa healing in a significant portion of patients.\textsuperscript{22-24} Anti-TNF therapy is associated with a lower rate of complications of CD in the short and long term, reduction of rates of hospitalization and surgery, and a significant improvement in quality of life.\textsuperscript{22,24} On the other hand, some studies have demonstrated an association between biological therapy and changes in metabolic profile (e.g. hypertriglyceridemia, change in LDL composition, increase in HDL), and weight gain, mainly at the expense of increased abdominal and visceral fat.\textsuperscript{25}

Since anti-TNF therapy controls the inflammatory state and induces remission in moderate to severe CD, it is possible that after this intervention an increase in body weight, LM and PA of these patients may be observed. In this context, our study was designed to evaluate the impact of anti-TNF\(\alpha\) therapy on body composition and PA in patients with active CD.

**Method**

In the period from April 2013 to August 2015, patients with moderate to severe CD with indication of anti-TNF therapy (infliximab – IFX) from the Intestinal Inflammatory Disease Outpatient Clinic of the Federal University of Juiz de Fora were included consecutively in our prospective study for the evaluation of body composition using BIA.

The study protocol was defined in accordance with the Declaration of Helsinki and approved by our Institutional Ethics Committee. All patients signed the informed consent form, before being accepted in the study.

The diagnosis of CD was established based on clinical, endoscopic, histopathological or imaging data.\textsuperscript{24} Patients aged between 18 and 65 years with moderate to severe CD, refractory or dependent on corticosteroids were included. Exclusion criteria were: severe comorbidities, gestation and/or concomitant infection. All patients underwent induction therapy with IFX (5 mg/kg at weeks 0, 2 and 6) followed by maintenance every 8 weeks. Patients who did not respond to anti-TNF therapy were excluded from the analysis.

At baseline, medical history and eligibility criteria were assessed. Relevant data such as age, gender, BMI and smoking habit were noted. Variables associated with the disease included duration, location and phenotype according to the Montreal Classification,\textsuperscript{26} therapy and previous history of surgery.

Disease activity was established according to the Harvey-Bradshaw Index (HBI). Moderate to severe cases were considered as active disease if HBI > 8, either associated or not with the presence of extensive and profound ulcers on colonoscopy, complications (e.g., stenosis, fistulas or abscess) and/or complex perianal disease. Biochemical parameters such as complete blood count, ESR,
l lipid profile, triglycerides, blood glucose, ferritin and albumin were evaluated.

**Anthropometry and body composition**

Patients should wear light clothing and be barefoot for the measurement of anthropometric data. Height was measured in centimeters (cm) rounded to the nearest 0.5 cm, and weight was measured in kilograms (kg) rounded to the nearest 0.1 kg. LM, FM and PA were obtained by electrical bioimpedance (Quantum BIA-101Q, Detroit, MI). Impedance measurements were performed on the right side, with the patient in the supine position, and the limbs apart from each other. We used a previously validated regression equation to analyze LM.\(^\text{19,27}\) The LM and FM indexes are calculated by dividing the LM and FM by the squared height, respectively. PA is a derived measure obtained from the relation between the direct measures of resistance and reactance. It is calculated directly from reactance and resistance:\(^\text{28}\)

\[
PA = \text{arc tangent (reactance / resistance) } \times \frac{180^\circ}{\pi}
\]

PA occurs when a portion of the electric current is stored by the cell membranes, creating a phase shift.\(^\text{29}\) In a healthy individual, PA can range from 4 to 10 degrees.\(^\text{8,30}\)

**Physical Activity Assessment Questionnaire**

The level of habitual physical activity (HPA) in daily life was assessed using the questionnaire activity described by Baecke et al.,\(^\text{27}\) and validated for the Brazilian population.\(^\text{28}\) This instrument is composed of 16 questions that cover three components of physical activity: 1) occupational physical activity score (Q1 to Q8); 2) leisure-time physical activity score (Q9 to Q12); and 3) leisure-time activities and locomotion score (Q13 to Q16). Together, these three domains, work, sports and non-sporting leisure, result in a global physical activity score. Scores ranging from 9 to 16 indicate a moderate level of daily physical activity, while scores < 9 are observed in sedentary individuals.\(^\text{31}\)

**Statistical analysis**

Sample size was calculated considering a type I error set at 0.05 and a sample power at 0.9 to detect a 1.5 kg LM difference in patients with CD before and after treatment with anti-TNF\(\alpha\). Thus, 25 patients would be needed for the study.

The collected data were analyzed using specific statistical software (SPSS- Statistical Package for the Social Sciences™, v. 13.0). For intra-group comparison in the active disease (baseline) and remission phases (in the 6th month), paired Student’s t-test or Wilcoxon test were performed. Pearson or Spearman correlation was used to assess the degree of association between variables. The type I error probability was assumed to be 5% in all tests.

**Results**

Of the 26 patients selected for the study, three were excluded: one did not attend the reevaluation visit, one had morbid obesity and one did not respond to IFX induction therapy.

Table 1 shows the demographic and clinical characteristics of patients with CD.

Six months after IFX therapy, there was a significant reduction in HBI score (7 versus 2; \(p<0.0001\)), as well as complete withdrawal of corticosteroids (35% versus 0%; \(p<0.0018\)).

Table 2 shows the laboratory data, anthropometric values and body composition. Based on BMI, most patients were classified as having normal weight both at baseline and after 6 months, despite an increase in BMI observed after treatment with IFX (22.9 versus 24.9; \(p=0.000\)).

In the analysis of body composition, we observed an increase in all parameters, except PA (Figure 1). Although baseline and post-intervention PA values were similar, they were significantly lower than the predicted values (predicted PA: 6.8°; baseline PA: 5.6° and post-intervention PA: 6.1°).

Data presented as mean and standard deviation or median and interquartile range; WC: waist circumference; * LMI: lean mass index, lean mass (kg) divided by squared height; † FMI: fat mass index, fat mass (kg) divided by squared height.

In relation to the level of habitual physical activity of the patients, low levels of habitual physical activity were observed in the baseline evaluation and after the intervention, even after achieving disease remission (6.2 vs. 6.8; p=0.94).

**DISCUSSION**

Biological therapy is a milestone in the treatment of IBDs. Anti-TNF agents have become drugs of choice in the treatment of patients with moderate to severe CD who do not tolerate the usual therapy. TNF-α is an inflammatory cytokine with catabolic power and a lipolytic and apoptotic effect that plays a significant role in lipid and glucose metabolism.

The efficacy of anti-TNFα agents in controlling the inflammatory process of IBD is indisputable. However, its effects on the body composition of patients with CD are still controversial. In our study, 20 (87%) of 23 patients had an increase in total body weight and, in 9 (39.1%), BMI values increased above 24.9, which is indicative of overweight/obesity. With regard to body composition, an increase in the LM (17.5±1.2 versus 18.1±2.3; p=0.000)
and FM indexes (5.5±2.3 versus 6.8±2.3; p=0.000) was observed. Vandan et al. evaluated 30 patients with CD undergoing IFX therapy and observed weight gain and change in nutritional status, the latter associated with clinical remission of the disease.29 Weight gain after biologic therapy has also been observed in other studies in patients with autoimmune diseases, suggesting that this therapy, and not simply the remission of CD, is associated with these changes in weight.30,32,33

Our results demonstrated that there was a substantial increase in FM after the use of IFX. It should be noted that all patients had the body water percentage within normal values, so that FM and LM could not be affected by disturbances in the patients’ hydration status.21 Increased FM after treatment with anti-TNF in patients with CD has also been reported in the study by Wiese et al.34 The gain of FM in patients who achieved clinical remission after biological therapy can be explained by factors such as improvement in the quantity and quality of food intake due to absence of symptoms, less catabolism secondary to reduction of inflammation and, last, TNF-α blockade. TNF is a mediator of cachexia induced by inflammation.32 In addition, inhibition of TNF-α may trigger an increase in the number of adipocytes by facilitating adipogenesis, resulting in increased FM.8

It should be noted that IFX therapy resulted in increased waist circumference (88.1±6.7 vs. 93.9±7.7 cm; p<0.05) in our patients with CD. This finding makes us speculate whether the increase in waist circumference should be attributed to visceral or subcutaneous adiposity. Some studies using magnetic resonance imaging have shown an increase in abdominal fat volume in patients treated for 8 weeks with IFX, with homogeneous fat distribution between the visceral and subcutaneous compartments.35,36 Interestingly, the accumulation of mesenteric fat in patients with CD has been observed and demonstrated to be independent of steroid use.29,37

A low level of physical activity leads to the disuse of skeletal muscle and consequent atrophy, which may be a factor present in patients with CD. All of our patients had a low level of habitual physical activity at baseline, with no change after induction and maintenance of CD remission.

Data regarding the metabolic profile of patients with CD undergoing anti-TNF therapy are controversial.35,38-40 Popa et al. observed reduced levels of triglycerides after six months of anti-TNFα therapy in patients with rheumatoid arthritis.38 Similar to the findings of Parmentier-Decreuq et al., despite weight gain, we did not observe changes in our patients’ profile after anti-TNF therapy.35

If the belief that a good control of the inflammatory state can positively influence the lipid concentration.41 Some studies have suggested that in different chronic clinical conditions, the PA can be considered a marker of general health, nutritional status and prognosis.42,43 Reduced PA values are associated with unfavorable disease progression and poor prognosis. In our study, the values found for PA were significantly lower than the reference values, even after treatment with IFX. This lack of improvement after 24 weeks of IFX therapy may be explained by the time of intervention, which may not have been sufficient to produce substantial gain in the cell compartments of which PA is representative. Another factor to be considered is that PA decreases the greater the FM and the lower the LM. Although our patients gained LM, FM gain was even more substantial.

Our study has some limitations. First, although the electrical bioimpedance method is valid and reliable for body composition analysis, it consists of a bi-compartmental model, unable to measure visceral fat and subcutaneous fat. Although the method was influenced by the state of hydration (e.g., chronic or cirrhotic renal patients), our patients maintained healthy hydration and, therefore, there was no impact of this factor on CD. Second, the sample size, although modest, was based on sample calculations, and was able to detect significant differences. And finally, the lack of a control group with healthy individuals did not allow comparisons with the patients.

Important clinical implications can be highlighted in the present study. In patients with active CD who achieved remission, there was a gain in LM and FM. However, fat gain was more significant with consequent nutritional disorder despite CD remission. In addition, considerable fat gain, the persistence of sedentary lifestyle even with disease in remission, and a significant increase in waist circumference suggest a possible increase in cardiovascular risk in these patients.

In conclusion, in patients with moderate to severe CD who achieved remission after 24 weeks of anti-TNF therapy, body weight gain was observed, attributed mainly to gain of FM, increased waist circumference and unchanged PA. Future studies should seek to assess the impact of fat gain on cardiovascular outcomes and overall health, as well as evaluate the effects of nutritional and physical activity interventions simultaneously with anti-TNFα treatment.

Resumo
Impacto da terapia biológica em portadores de doença de Crohn: Um estudo prospectivo

Introdução: Desnutrição proteico-calórica em pacientes de doença de Crohn (DC) tem sido relatada em 20 a 92% dos casos associando-se a maior morbimortalidade e maiores custos para o sistema de saúde. Agentes anti-TNF são um marco no controle clínico, promovendo remissão prolongada em portadores de DC. Acredita-se que a remissão da doença leve à recuperação nutricional desses pacientes. O efeito da terapia biológica na composição corpórea e no estado nutricional é pouco conhecido.

Método: Estudo prospectivo de avaliação corporal por método de bioimpedência em portadores de DC moderada a grave submetidos à terapia com infliximabe (IFX). O desfecho principal foi a composição corporal antes e após 6 meses de terapia anti-TNF.

Resultados: Houve predominio do sexo feminino (52%), com média de idades de 42±12 anos. A maioria dos pacientes era eutrófica na inclusão do estudo e assim permaneceu. Houve aumento de todos os parâmetros da composição corporal após o tratamento anti-TNF: IMC (22,9±3,2 versus 25±3,8; p=0,005), circunferência abdominal (88,1±6,7 versus 93,9±7,7; p=0,002), índice de massa magra (17,5±12,2 versus 18,2±2,3; p>0,000) e índice de massa gorda (5,5±2,3 versus 6,8±2,3; p=0,000). O ângulo de fase manteve-se inalterado (6,2 versus 6,8; p=0,94).

Conclusão: Após terapia com IFX, observou-se aumento de todos os componentes da composição corporal, exceto no ângulo de fase. O aumento substancial do índice de massa gorda e da circunferência abdominal levantam a preocupação de aumento nos riscos cardiovasculares e necessidade de estudos complementares.
